Ref: https://junyanz.github.io/CycleGAN/

• Let's consider a particular constrained set of classifiers (through origin)

$$h(x;\theta) = \operatorname{sign}(\theta_1 x_1 + \dots + \theta_d x_d) = \operatorname{sign}(\theta \cdot x) = \begin{cases} +1, & \theta \cdot x \ge 0 \\ -1, & \theta \cdot x < 0 \end{cases}$$

- $\theta \cdot x = \theta^T x$ and $\theta = [\theta_1, \dots, \theta_d]^T$ is a column vector of real valued parameters or weights.
- Different settings of the weights give rise to different classifiers.

$$h(x;\theta) = \operatorname{sign}(\theta_1 x_1 + \dots + \theta_d x_d) = \operatorname{sign}(\theta \cdot x) = \begin{cases} +1, & \theta \cdot x \ge 0 \\ -1, & \theta \cdot x < 0 \end{cases}$$

Linear classifier through origin:

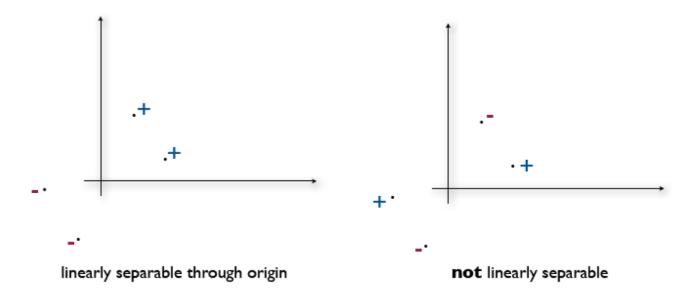

$$h(x;\theta) = \operatorname{sign}(\theta_1 x_1 + \dots + \theta_d x_d) = \operatorname{sign}(\theta \cdot x) = \begin{cases} +1, & \theta \cdot x \ge 0 \\ -1, & \theta \cdot x < 0 \end{cases}$$

Training error:

$$\mathcal{E}_n(\theta) = \frac{1}{n} \sum_{t=1}^n [[y^{(t)} \neq h(x^{(t)}; \theta)]] = \frac{1}{n} \sum_{t=1}^n [[y^{(t)}(\theta \cdot x^{(t)}) \leq 0]]$$

 Linear classifier that achieves zero training error is called realizable.

Definition 1.1 Training examples $S_n = \{(x^{(t)}, y^{(t)}), t = 1, ..., n\}$ are linearly separable through origin if there exists a parameter vector $\hat{\theta}$ such that $y^{(t)}(\hat{\theta} \cdot x^{(t)}) > 0$ for all t = 1, ..., n.

How do we find the weights such that they minimize the training error?

- Initialize the weights and the threshold.
- For each training example 't' in S_n , classify the instance
 - if the prediction was correct, continue
 - else, $\theta^{(k+1)} = \theta^{(k)} + y^{(t)}x^{(t)}$
- Terminate if the training error is less than the threshold or a pre-determined number of iterations are completed.

What does the update rule ($\theta^{(k+1)} = \theta^{(k)} + y^{(t)}x^{(t)}$) do?

- If the classifier predicted an instance that was negative but it should have been positive...
 - Currently: $\theta \cdot x < 0$
 - Want: $\theta \cdot x > 0$
- Adjust the weights θ so that this function values move toward positive.
- If the classifier predicted positive but it should have been negative, shift the weights so that the value moves toward negative.

• If a classification mistake is made on sample 't', i.e.,

$$y^{(t)}(\theta \cdot x^{(t)}) \le 0$$

The updated weight vector is:

$$\theta^{(k+1)} = \theta^{(k)} + y^{(t)}x^{(t)}$$

• With updated weights, $y^{(t)}(\theta^{(k)} \cdot x^{(t)})$ becomes more positive and eventually becomes > 0 in a realizable case.

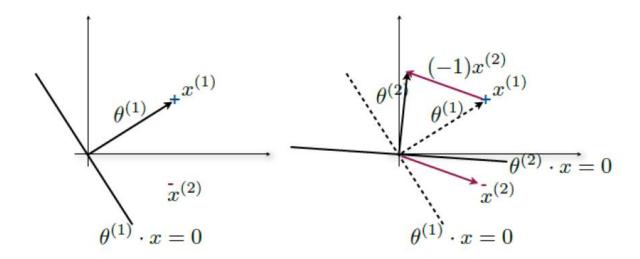

$$y^{(t)}(\theta^{(k+1)} \cdot x^{(t)}) = y^{(t)}(\theta^{(k)} + y^{(t)}x^{(t)}) \cdot x^{(t)}$$

$$= y^{(t)}(\theta^{(k)} \cdot x^{(t)}) + (y^{(t)})^{2}(x^{(t)} \cdot x^{(t)})$$

$$= y^{(t)}(\theta^{(k)} \cdot x^{(t)}) + ||x^{(t)}||^{2}$$

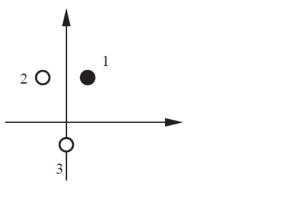

• **Example:** Given the update rule, $\theta^{(k+1)} = \theta^{(k)} + y^{(t)}x^{(t)}$

$$\theta^{(1)} = \theta^{(0)} + x^{(1)}$$
$$\theta^{(2)} = \theta^{(1)} + (-1)x^{(2)}$$

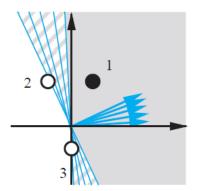

Theorem 2.1 The perceptron update rule converges after a finite number of mistakes when the training examples are linearly separable through origin.

Test example:

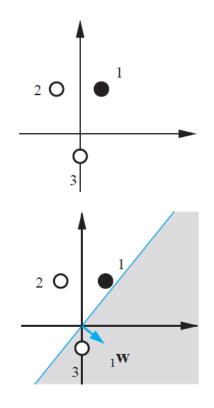

Input data

Weight vectors representing allowable decision boundaries

Test example:

$$x^{(1)} = \begin{bmatrix} 1 \\ 2 \end{bmatrix}, y^{(1)} = 1$$

$$x^{(2)} = \begin{bmatrix} -1 \\ 2 \end{bmatrix}, y^{(2)} = -1$$

$$x^{(3)} = \begin{bmatrix} 0 \\ -1 \end{bmatrix}$$
, $y^{(3)} = -1$

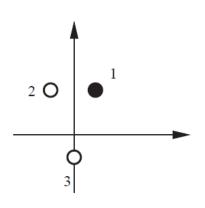

Perceptron update rule:

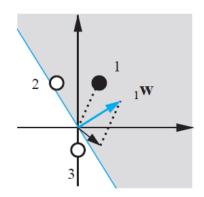

if
$$y(\theta \cdot x) \le 0$$
 then
$$\theta^{(k+1)} = \theta^{(k)} + y^{(t)}x^{(t)}$$

$$\theta^{(0)} = \begin{bmatrix} 1 \\ -0.8 \end{bmatrix}$$

→ Random weight initialization

Test example:

$$x^{(1)} = \begin{bmatrix} 1 \\ 2 \end{bmatrix}, y^{(1)} = 1$$

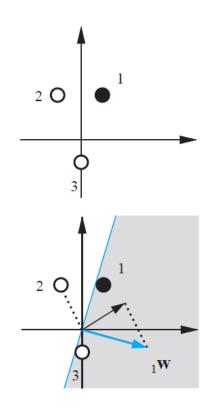

$$x^{(2)} = \begin{bmatrix} -1 \\ 2 \end{bmatrix}, y^{(2)} = -1$$

$$x^{(3)} = \begin{bmatrix} 0 \\ -1 \end{bmatrix}, y^{(3)} = -1$$

if
$$y(\theta \cdot x) \le 0$$
 then
$$\theta^{(k+1)} = \theta^{(k)} + y^{(t)}x^{(t)}$$

$$\theta^{(1)} = \begin{bmatrix} 2 \\ 1.2 \end{bmatrix}$$
 \rightarrow 1st Update

Test example:

$$x^{(1)} = \begin{bmatrix} 1 \\ 2 \end{bmatrix}, y^{(1)} = 1$$

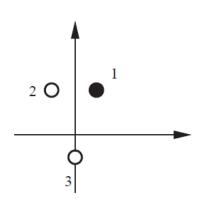

$$x^{(2)} = \begin{bmatrix} -1 \\ 2 \end{bmatrix}, y^{(2)} = -1$$

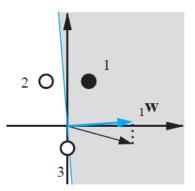

$$x^{(3)} = \begin{bmatrix} 0 \\ -1 \end{bmatrix}$$
, $y^{(3)} = -1$

if
$$y(\theta \cdot x) \le 0$$
 then
$$\theta^{(k+1)} = \theta^{(k)} + y^{(t)}x^{(t)}$$

$$\theta^{(2)} = \begin{bmatrix} 3 \\ -0.8 \end{bmatrix}$$
 \rightarrow 2nd Update

Test example:

$$x^{(1)} = \begin{bmatrix} 1 \\ 2 \end{bmatrix}, y^{(1)} = 1$$

$$x^{(2)} = \begin{bmatrix} -1 \\ 2 \end{bmatrix}, y^{(2)} = -1$$

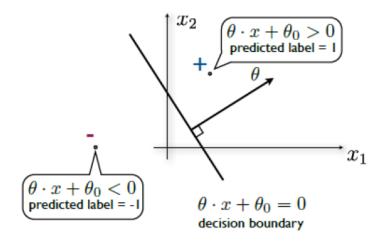

$$x^{(3)} = \begin{bmatrix} 0 \\ -1 \end{bmatrix}, y^{(3)} = -1$$

if
$$y(\theta \cdot x) \le 0$$
 then
$$\theta^{(k+1)} = \theta^{(k)} + y^{(t)}x^{(t)}$$

$$\theta^{(3)} = \begin{bmatrix} 3 \\ 0.2 \end{bmatrix} \rightarrow 3^{rd} Update$$

$$h(x; \theta, \theta_0) = \operatorname{sign}(\theta \cdot x + \theta_0) = \begin{cases} +1, & \theta \cdot x + \theta_0 \ge 0 \\ -1, & \theta \cdot x + \theta_0 < 0 \end{cases}$$

- The hyper-plane $\theta \cdot x + \theta_0 = 0$ is **oriented parallel** to $\theta \cdot x = 0$
- Whereas, θ is still **orthogonal** to the decision boundary and $\theta_0 < 0$

 Example: Suppose we want to predict whether a web user will click on an ad for a refrigerator

Four features:

- Recently searched "refrigerator repair"
- Recently searched "refrigerator reviews"
- Recently bought a refrigerator
- Has clicked on any ad in the recent past
- These are all binary features (values can be either 0 or 1)

Suppose these are the weights

Searched "repair"	2.0
Searched "reviews"	8.0
Recent purchase	-15.0
Clicked ads before	5.0
b (intercept)	-9.0

Evaluate the linear classifier with offset

$$h(x; \theta, \theta_0) = \begin{cases} +1, & \theta \cdot x + \theta_0 \ge 0 \\ -1, & \theta \cdot x + \theta_0 < 0 \end{cases}$$

Suppose these are the weights

Searched "repair"	2.0
Searched "reviews"	8.0
Recent purchase	-15.0
Clicked ads before	5.0
b (intercept)	-9.0

•
$$\theta \cdot x + \theta_0 = (2 * 0) + (8 * 1) + (-15 * 0) + (5 * 0) + (-9)$$

= $8 - 9 = -1$

Prediction = No

Searched "repair"	2.0
Searched "reviews"	8.0
Recent purchase	-15.0
Clicked ads before	5.0
b (intercept)	-9.0

- $\theta \cdot x + \theta_0 = (2 * 1) + (8 * 1) + (-9) = 1$
- Prediction = Yes

Searched "repair"	2.0
Searched "reviews"	8.0
Recent purchase	-15.0
Clicked ads before	5.0
b (intercept)	-9.0

- $\theta \cdot x + \theta_0 = (8 * 1) + (5 * 1) + (-9) = 4$
- Prediction = Yes

Searched "repair"	2.0
Searched "reviews"	8.0
Recent purchase	-15.0
Clicked ads before	5.0
b (intercept)	-9.0

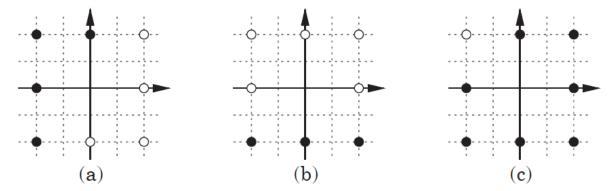

- $\theta \cdot x + \theta_0 = (8 * 1) + (-15 * 1) + (5 * 1) + (-9) = -11$
- Prediction = No
- If someone bought a refrigerator recently, they probably aren't interested in shopping for another one anytime soon.

Searched "repair"	2.0
Searched "reviews"	8.0
Recent purchase	-15.0
Clicked ads before	5.0
b (intercept)	-9.0

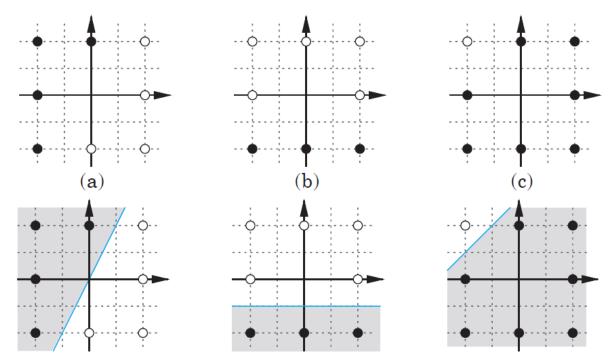

- $\theta \cdot x + \theta_0 = -9$
- Prediction = No
- Since most people don't click ads, the "default" prediction is that they
 will not click (the intercept pushes it to negative).

 If training examples are linearly separable through origin, they are also linearly separable with offset. Is the converse true? Why not?

 If training examples are linearly separable through origin, they are also linearly separable with offset. Is the converse true? Why not?

 If training examples are linearly separable through origin, they are also linearly separable with offset. Is the converse true?
 Why not?

- Initialize the weights and the threshold.
- For each training example 't' in S_n , classify the instance
 - if correct, continue
 - else, $\theta^{(k+1)} = \theta^{(k)} + y^{(t)}x^{(t)}$ $\theta_0^{(k+1)} = \theta_0^{(k)} + y^{(t)}$
- Terminate if the training error is less than the threshold or a pre-determined number of iterations are completed.

Intended Learning Outcomes

 Given a set of training examples, find out if they are linearly separable.

 Use of Perceptron algorithm to select the best classifier in a realizable case.

Application of the Perceptron algorithm to real data.
